THE RISK SENSITIVITY OF GLOBAL LIQUIDITY FLOWS: HETEROGENEITY, EVOLUTION AND DRIVERS

by Stefan Avdjiev*, Leonardo Gambacorta*, Linda S. Goldberg** and Stefano Schiaffi***

Abstract

The period after the Global Financial Crisis (GFC) was characterized by a considerable risk migration within global liquidity flows, away from cross-border bank lending towards international bond issuance. We show that the post-GFC shifts in the risk sensitivities of global liquidity flows are related to the tightness of the (capital and liquidity) constraints faced by international (bank and non-bank) lenders and to the migration of borrowers across funding sources. We show that the risk sensitivity of global liquidity flows is higher when funding is provided by financial intermediaries that are facing greater balance sheet (capital and leverage) constraints. We also provide evidence that the post-GFC migration of borrowers from cross-border loans towards international debt securities was associated with a decline in the risk sensitivity of global liquidity flows and their main components.

1 Introduction

The Global Financial Crisis (GFC) marked a stark turning point for the volumes, volatility and drivers of cross-border loans (CBL) and international debt securities (IDS), jointly defined as aggregate global liquidity (AGL). The initial sharp decline in cross-border loans after the GFC was followed by a weak recovery and a second sizable contraction during the peak of the euro area crisis. Meanwhile, growth in international bond issuance remained relatively robust, tilting the balance of international financial flows toward bonds and away from loans.

The post-GFC shift in the relative importance of the two main global liquidity components has occurred simultaneously with considerable shifts in their sensitivities to global risk (Avdjiev, Gambacorta, Goldberg, and Schiaffi, 2020). The risk sensitivity of cross-border bank lending declined sharply. By contrast, international bond issuance remained highly sensitive to global risk conditions. Forbes and Warnock (2021) describe the risk sensitivities of global capital flows as having evolved from behaving like waves to appearing more as ripples, based on data through 2020, with sudden stop episodes less pervasive in the latter decade and more associated with debt than with equity events. More generally, research shows that the drivers and features of these main components of global liquidity, as the core of the global factor stressed in international finance (Rey, 2015), are key inputs into discussions of international shock transmission and the degree of policy autonomy of countries participating in international financial markets (Bank for International Settlements, 2022; International Monetary Fund, 2020; OECD, 2024).

In this paper, we investigate the drivers of sensitivities and determinants of the risk migration within global liquidity flows that took place after the GFC. We examine the shifting drivers of global liquidity across its main components (cross-border loans and international bonds), as well as across borrowing country groups (Advanced Economies and Emerging Market Economies) and borrowing sectors (bank sector and non-bank sector). We explicitly separate patterns of so-called safe haven countries from other advanced economies (OAEs). Understanding the nature of the heterogeneity across the above dimensions is key for properly assessing the exposure of economies to global shocks as well as the scope for local toolkits to appropriately target financial flows and institutions in order to support economic and financial stabilization (Borio, Robinson, and Shin, 2023).

Our analysis proceeds in several steps. We start by documenting the notable shift in international financial intermediation away from cross-border bank lending and towards international bond issuance that has taken place after the GFC. We then present empirical evidence of the significant variation in global risk sensitivities not only over time, but also across global liquidity components (cross-border loans and international debt securities), borrowing country groups (advanced economies, emerging markets) and sectors (banks, non-banks). We then drill deeper into the sources of heterogeneity in global risk sensitivities across all of the above dimensions by investigating the underlying drivers, with a particular focus on financial frictions. We conjecture that tighter capital and leverage constraints faced by the bank and non-bank financial institutions (NBFI) serving as global financial intermediaries increase the sensitivity of their international credit supply to global risk shocks. These constraints are influenced by financial regulation, which in turn has an effect on migration of risky borrowers between banks and NBFIs.

Our empirical analyses utilize a number of datasets to yield the granularity needed for testing the above conjectures. For global liquidity flows, from the Bank for International Settlements (BIS), we utilize the International Debt Securities (IDS) Statistics, the Locational Banking Statistics (LBS) and the Consolidated Banking Statistics (CBS). The combined information allows the distinction among borrowing countries, lending national banking systems, instrument types (debt securities versus bank loans) and borrowing sectors (bank versus non-bank). Graph 1 displays the evolution of the main global liquidity flow components since the start of the century taking an aggregate perspective. It illustrates that international financial intermediation has clearly shifted away from bank-based (red areas) to market-based (blue areas) financing. International bond issuance has surged, most notably by non-bank borrowers (which include non-financial corporations and sovereigns) in emerging market economies (EMEs). By contrast, cross-border bank lending has stagnated, especially to borrowers in advanced economies (AEs).

Graph 1: The evolving composition of external debt flows

Notes: Amounts outstanding, in trillions USD. Sources: BIS Locational Banking Statistics by residence and International Debt Securities Statistics.

As flows embed the characteristics of institutions involved in international financial intermediation, our analysis also incorporates information on lending banking systems' balance sheet characteristics, drawn from BankScope, and new measures that we have constructed to capture the characteristics of the NBFIs that are active in international bond markets. Data on NBFI characteristics and international activity are more sparse than the respective data on banks. To address this gap, we utilize a novel approach that leverages on the annual NBFI data collection exercise

of the Financial Stability Board (FSB) and is targeted at constructing various NBFI vulnerability metrics, while conditioning on the business model of each data-reporting institution (Financial Stability Board, 2024).

The primary focus of our empirical analysis is on the sensitivity of the main global liquidity components to risk conditions, captured by the VIX (as well as other global risk measures considered for robustness). Additionally, monetary policy developments enter our analysis, including the use of shadow policy rates during periods of unconventional monetary policy and periods during which the zero lower bound is binding.

Our empirical analysis produces novel sets of results on the risk sensitivity of global liquidity flows. First, time variation is shown to be a pervasive feature of risk sensitivities of the main global liquidity components. Furthermore, there is considerable heterogeneity in the evolution of the global risk sensitivities across several key dimensions of global liquidity-flow type, borrowing country and borrowing sector. Declines have been strongest in cross-border lending. The sensitivity of CBL to global risk drifted from being significantly negative before the GFC—meaning that loan supply would contract significantly when the risk environment deteriorated–to becoming statistically insignificant after the GFC. The global risk sensitivity of IDS issued by EME borrowers increased further after the GFC and then partially reverted, but remained considerably elevated. The global risk sensitivity of IDS issued by OAEs residents was insignificant throughout the entire period we examine.

Second, the evolutions in the risk sensitivities of global liquidity flows are related to the tightness of the balance-sheet constraints faced by international (bank and non-bank) financiers and to the migration of risk between CBL and IDS markets. The post-GFC tightening of bank regulation provided global banks with extra risk absorbing capacity while raising the balance sheet cost of risky bank loans. As banking sectors with tighter capital constraints (lower rates of bank capitalization) have significantly higher risk sensitivities, riskier borrowers migrated to IDS markets, where funding is mainly provided by NBFIs.

Third, we document that the migration of borrowers from CBL to IDS markets is associated with lower global risk sensitivities of CBL and IDS flows. Intuitively, as banks move away from serving borrowers that are riskier than their average borrowers, the average riskiness of bank borrowers falls. Meanwhile, the global risk sensitivity of IDS also declines if the borrowers that migrate from

CBL to IDS markets are less risky than the average IDS borrower. These two (risk composition) effects dominate the mechanical effect of the increasing weight of IDS flows, which tend to be riskier than CBL flows. As a consequence, the global risk sensitivity of AGL flows also declines when the IDS share of global liquidity rises.

An important implication of our findings is that some of the post-GFC dampening in the global risk sensitivity of aggregate global liquidity flows may be reversed. More stringent bank capital regulation has led to risk migration from (bank-supplied) loans to (primarily NBFI-supplied) bond-based finance. Given our estimates of risk sensitivities for non-bank borrowers in emerging markets, a continued rise in the NBFI-supplied share of global liquidity could move the global risk sensitivity of aggregate global liquidity flows back towards pre-GFC levels. This could happen if, at some point in the future, the mechanical effect dominates the risk composition effect. However, as borrowers migrate from CBL to IDS markets, both the mechanical and risk composition channels are likely to become stronger, with uncertain aggregate effects. The mechanical effect will become stronger simply because the share of total liquidity intermediated through IDS will increase as borrowers migrate. The risk composition effect would also become stronger because the marginal borrower migrating from CBL to IDS markets is likely to become less risky over time, thereby decreasing the risk sensitivity of IDS.

The remainder of the paper is organized as follows. Section 2 reviews the existing literature and presents the main conjectures that we test in our empirical analysis. Section 3 presents the main databases used in our empirical analysis. Section 4 examines the evolution of the global risk sensitivities for the main global liquidity components. Section 5 presents our findings on the determinants of the risk migration within global liquidity flows that took place after the GFC. This section emphasizes the importance of the balance sheet constraints faced by internationally active (bank and non-bank) financial institutions and the migration of risk between CBL and IDS markets. Section 6 presents robustness checks along a number of key dimensions. Section 7 concludes.

2 Related Literature and Conjectures

2.1 Related literature

Several strands of literature consider the drivers of international flows, risk sensitivities and migration, and the evolving role of nonbank financial intermediaries. The large early body of research on the drivers of international capital flows,[1] splits the main drivers into global (push) factors and local (pull) factors. The more recent literature emphasizes the common component reflected in the global financial cycle as argued by Rey 2015), with the most prominent global drivers including advanced economy monetary policies - especially US monetary policy, global risk aversion, and global economic activity. Local factors include the borrowing country's GDP growth, sovereign ratings, and financial openness.

The spillovers of US monetary policy have been those most extensively examined (see Buch, Bussiere, Goldberg, and Hills (2019); Caballero and Upper (2023); Arteta, Kamin, and Franz Ulrich (2022) for recent summaries). US monetary policy clearly drives cross-border bank lending through global banks for EMEs, as in Avdjiev and Hale (2019) and Bräuning and Ivashina (2020). US monetary policy significantly impacts multiple other key economic and financial variables in EMEs - local-currency bond yields (Frankel, Schmukler, and Serven, 2004; Hofmann and Takáts, 2015; Kalemli-Özcan, 2019; **?**; Kharroubi and Zampolli, 2016), foreign-currency bond yields (Gilchrist, Yue, and Zakrajšek, 2019), domestic economic activity (Iacoviello and Navarro, 2019), and equity markets (Ehrmann and Fratzscher, 2004). Effects work broadly through potential expenditure switching, expenditure reduction, and have consequences through financial channels. The sensitivity of global liquidity flows to US monetary policy across a broad group of economies - a combination of advanced and emerging market economies - rose substantially in the immediate aftermath of the GFC, peaked around the time of the 2013 Fed "taper tantrum", and then reverted towards pre-crisis levels (Avdjiev, Gambacorta, Goldberg, and Schiaffi, 2020). The main driver of the evolution of the estimated sensitivities of global liquidity to US monetary policy was the degree of convergence among monetary policies of advanced economies. Kalemli-Özcan and Unsal (2023) Cristi, Kalemli-Özcan, Sans, and Unsal (2024)

Global risk conditions are the other historically major driver of cross-border capital flows.

[1] See overview by Koepke (2019)

A global financial cycle in capital flows, asset prices and in credit growth co-moves with market uncertainty and risk aversion (Rey, 2015). Global risk sentiment, often typically proxied by the VIX, is a documented major global driver of international capital flows and, in particular, of cross-border bank lending (e.g. Bekaert, Hoerova, and Duca 2013; Bruno and Shin 2015a,b; Miranda-Agrippino and Rey 2020; Chari, Dilts Stedman, and Lundblad 2021; Bank for International Settlements 2017). Some studies highlight the importance of dollar exchange rates as a reflector of global risk sentiment (Bruno and Shin, 2015b). The global risk sensitivity of cross-border bank flows has declined considerably since the GFC (Shin, 2016), driven in part by increases in the international lending shares of better-capitalized banking systems (Avdjiev, Gambacorta, Goldberg, and Schiaffi, 2020). Meanwhile, global shocks are increasingly in focus for their impacts on the full distributions (rather than just the means) of asset prices associated with international capital flows, with tail risk effects for EMEs (Chari, 2023). Macroprudential stance can alter the effects of risk-on and risk-off shocks on bond flows (Chari, Dilts Stedman, and Forbes, 2022).

Much of the literature treats the consequences of global risk conditions as distinct for advanced and emerging market economies, as different financial frictions, institutions, and risk assessments characterize associated borrowers and lenders. Yet, the rigid distinction between these two groups may no longer be valid. Goldberg and Krogstrup (2023), using correlations between exchange market pressure indices and the VIX, argue that advanced economies are no longer a cohesive group. In contrast to the pre-GFC period, advanced economies are divided into the few so-called safe-haven countries that receive inflow and appreciation pressures when risk sentiment deteriorates, versus all of the other advanced economies that may have more in common with emerging markets in experiencing outflow pressures during such stress periods (Goldberg, 2023). A complementary conceptual point arises from the rich literature on convenience yields on government debt and covered interest parity deviations after the GFC. Global liquidity and safe haven flows in periods of elevated risk characterize just a few currencies, inclusive of US dollar assets (Nagel, 2016; Du, Tepper, and Verdelhan, 2018; Krishnamurthy and Vissing-Jorgensen, 2012; van Binsbergen, Diamond, and Grotteria, 2022).

Another relevant literature emphasizes the stark compositional change in the types of institutions involved in financial intermediation. NBFIs have a growing role in the aggregate supply of credit in the economy (Moreira and Savov, 2017; Buchak, Matvos, Piskorski, and Seru, 2018;

Elliott, Meisenzahl, and Peydró, 2024; Mehrling, Pozsar, Sweeney, and Neilson, 2013; Chen, Ren, and Zha, 2018; Nelson, Pinter, and Theodoridis, 2018; Fuster, Plosser, Schnabl, and Vickery, 2019; Irani, Iyer, Meisenzahl, and Peydró, 2020). Moreover, on the international side, the declining share of bank-intermediated credit in total capital inflows has been mirrored by the growing importance of market-based flows (see, for example, Shin (2014)). This rising share of NBFIs in international capital flows has been driven primarily by the growing roles of open-ended investment funds, pension funds, life insurers, hedge funds, and sovereign wealth funds (Financial Stability Board, 2022). Regulatory arbitrage, and possible risk migration, have been documented for some dimensions of global banking activity, for example as Houston, Lin, and Ma (2012); Frame, Mihov, and Sanz (2020) consider the location of bank subsidiaries, and Demirgüç-Kunt, Horváth, and Huizinga (2023) examine syndicated loan origination in response to more stringent capital origination. NBFIs in cross-border capital flows have diversified the sources of international financing and are argued to improve access to foreign financing and reduce the cost of capital (Bank of England, 2015). Non-bank lenders can act as global shock absorbers from US monetary policy spillovers (Elliott, Meisenzahl, and Peydró, 2024).

However, open for debate is whether NBFI-intermediated flows may be more sensitive to global financial conditions and may have introduced additional procyclicality into capital flows to EMEs (Carney, 2019; Bertaut, Bruno, and Shin, 2021; Converse, Levy-Yeyati, and Williams, 2023). The greater sensitivity of NBFI flows to global factors is argued to likely be driven by benchmark-driven investors (Arslanalp, Drakopoulos, Goel, and Koepke 2020; Chari 2023). Raddatz, Schmukler, and Williams (2017) find that 70% of country allocations of mutual funds are influenced by benchmark indices. Arslanalp, Drakopoulos, Goel, and Koepke (2020) show that the sensitivity of flows from benchmark driven investors to global risk is three to five times greater than that of aggregate portfolio flows. Aldasoro, Doerr, and Zhou (2022) show that NBFIs cut their credit by significantly more than banks during financial crises and argue that the growing importance of NBFIs could lead to a shift from relationship towards transaction lending, thus exacerbating the repercussions of financial crises. Faia, Salomao, and Veghazy (2024) show that different types of European investors have alternative portfolio constraints and preferences across assets by risk and currency denomination.

2.2 Conjectures

We present two main conjectures on the drivers of the time variation in the risk sensitivity of global liquidity flows.

Our first conjecture is related to the balance sheet constraints faced by the financial institutions supplying global liquidity. In theory, the tighter balance sheet constraints are, the more sensitive should financial intermediaries be to risk shocks. Therefore, the risk sensitivity of global liquidity flows should depend on the tightness of the balance sheet constraints faced by the financial institutions providing those flows.

Conjecture 1. The risk sensitivity of global liquidity flows is stronger when funding is (in aggregate) provided by financial intermediaries that are facing greater balance sheet (capital and leverage) constraints.

Our second conjecture is related to the migration of risk between the two main global liquidity components - cross-border loans (CBL) and international debt securities (IDS). In theory, such risk migration should have two effects on the risk sensitivity aggregate global liquidity (AGL) flows.

The first effect is compositional. If banks become more conservative and stop serving borrowers that are riskier than their average borrowers, the CBL sensitivity to global risk should decline (since the average riskiness of bank borrowers would fall). Furthermore, the global risk sensitivity of IDS should also decline, if the borrowers that are no longer served by banks are less risky than the average IDS borrower (despite being riskier than the average bank borrower).[2]

The second effect is mechanical. If borrowers start migrating from CBL to IDS markets, the share of IDS in AGL flows should increase. As a consequence, the sensitivity of AGL flows to global risk could potentially increase mechanically, due to the higher weight of IDS, which tend to be more risk sensitive than cross-border bank loans, at least for certain borrowing groups and time periods.

Thus, the migration of risk from CBL to IDS markets should (unambiguously) result in a decline in the global risk sensitivities of CBL and IDS flows (due to the compositional effect described above). Meanwhile, the impact of risk migration on AGL flows would depend on which of the above two effects dominates. If the compositional effect dominates the mechanical effect, the global

[2]This is a very likely scenario since IDS borrowers tend to be riskier than CBL borrowers, as evidenced by the fact that the global risk sensitivity of IDS flows tends to be substantially greater than that of CBL flows.

risk sensitivity of AGL flows should decline and vice versa.

Conjecture 2. As borrowers migrate from CBL to IDS markets, the global risk sensitivities of CBL and IDS flows should fall. This should result in a decline in the global risk sensitivity of AGL flows, if the compositional effect of risk migration dominates its mechanical effect and vice versa.

3 Global liquidity and Financial Institution Characteristics

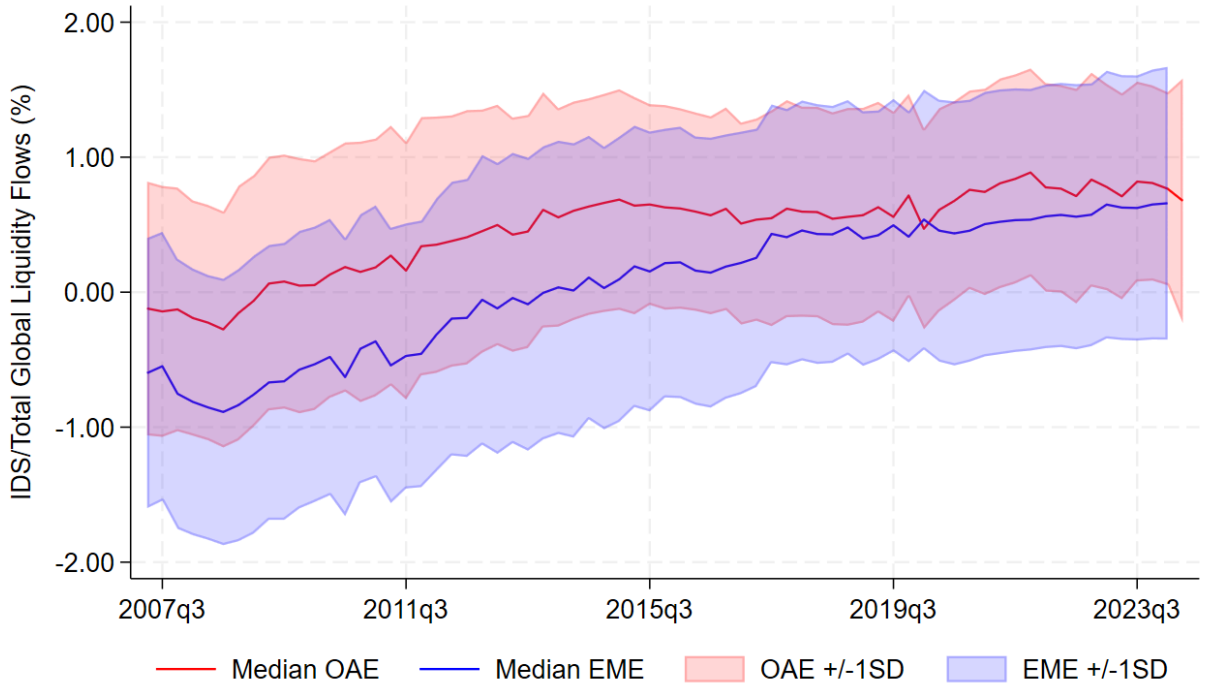
3.1 The main components of global liquidity

Three databases capture the dimensionality we need to explore the main components of global liquidity: the BIS Locational Banking Statistics (LBS), the BIS International Debt Securities Statistics (IDSS), and the BIS Consolidated Banking Statistics (CBS). The BIS LBS captures the outstanding claims and liabilities of internationally active banks located in 44 BIS LBS reporting countries against counterparties residing in more than 200 countries. Banks record their positions on an unconsolidated basis, including intragroup positions to capture international flows between offices of the same banking group. The data, which are aggregated at the country level and compiled following balance of payments statistics principles, capture around 95% of all cross-border interbank business (Bank for International Settlements, 2024). The counterparty sector breakdown available in the BIS LBS enables us also to distinguish between cross-border bank lending to bank and non-bank borrowers. The BIS CBS is used in order to obtain information on the relative importance of lending countries for a given borrowing country. The BIS IDSS data capture borrowing in money and bond markets, encompassing what market participants have traditionally referred to as foreign bonds and eurobonds. International debt securities (IDS) are issued in a market other than the local market of the country where the borrower resides (Gruić and Wooldridge, 2012). The sample used for the empirical analysis consists of quarterly data from Q1 2000 to Q1 2024. On the borrowing side, our analytics focus on a set of 61 countries; on the bank lending side, data cover the positions of all 44 BIS LBS and 31 CBS reporting countries (see Appendix A).

The typical lenders and borrowers connected by each flow type differ considerably in composition and size (Avdjiev, Gambacorta, Goldberg, and Schiaffi, 2020). Cross-border loans are typically supplied by internationally-active banks, which tend to be relatively large. Meanwhile, the creditors in international debt securities markets are usually non-bank financial intermediaries, such as

pension funds, insurance companies, money market mutual funds, and hedge funds. The variation on the borrower side is even greater. International bond issuance by non-banks tends to be dominated by sovereigns and large non-financial corporations. The latter are also important players on the borrowing side of the cross-border bank loan market, which also channels funds to exporting and importing firms and leveraged non-bank financials. (See descriptive statistics in Table A1 in the Appendix). Countries differ greatly in their experiences, as illustrated in Graph 2 which shows the distributions across countries of shares of international debt securities in total inflows of loans and debt securities financing at each point in time. The median IDS shares rose for both OAEs and EMEs during the decade following the GFC, with the steepest increases for EMEs. By the 2020s, the median shares of IDS for EMEs caught up to those for the other advanced economies, although with greater variation across EMEs.

Graph 2: IDS Share in Global Liquidity of Borrowing Countries



Notes: Median share of the demeaned International Debt Securities in Total Global Liquidity Flows for each borrowing country in our sample, with a one standard deviation (SD) band, by OAEs and EMEs, for 2007Q1-2024Q1.

3.2 Bank and NBFI characteristics

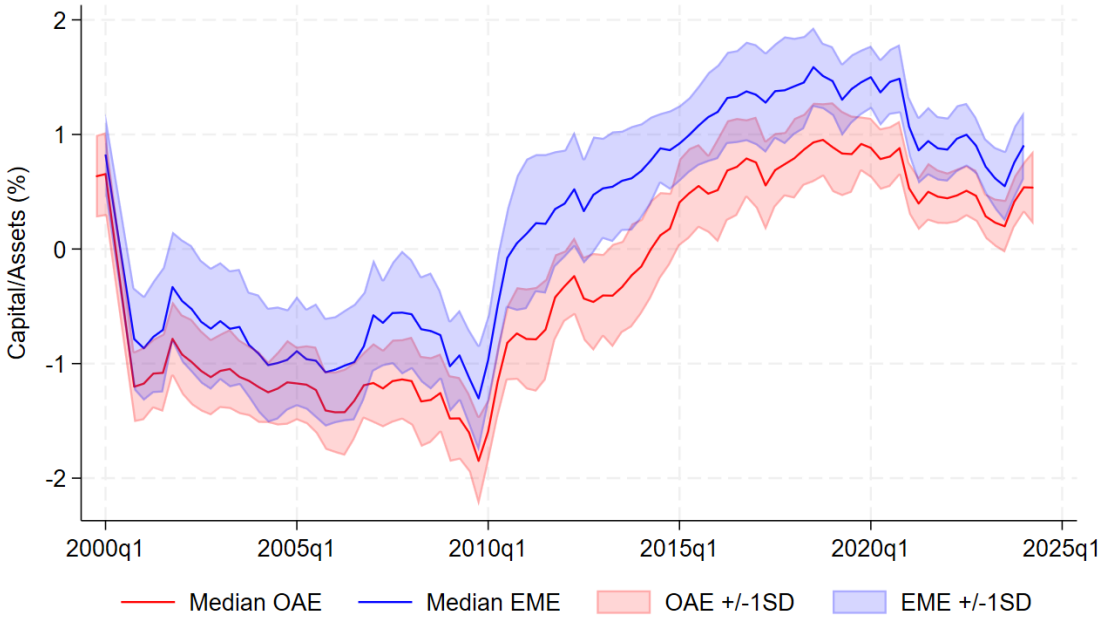
The balance sheets and business models of the financial intermediaries involved in these flows, important for shock sensitivities, have evolved post GFC. Following Avdjiev, Gambacorta, Goldberg, and Schiaffi (2020), we construct the balance sheet characteristics of national banking systems using BankScope data. We obtain the balance sheet items of interest for the set of internationally active banks that report to the BIS consolidated banking statistics, and then aggregate bank-level characteristics to national banking system-wide variables, using total asset-weighted averages across the individual banks of a given nationality. Data are adjusted for mergers and acquisitions to correct for balance sheet jumps that are unrelated to lending (Brei, Gambacorta, and Von Peter (2013)). Our benchmark analysis has a primary focus on bank capitalisation, measured as the ratio of bank capital to total assets. A key point is that the relevant banking sector characteristics are those that map to the perspective of the recipient country of global liquidity flows, and thus these are a borrowing country-time weighted average of the characteristics across lending banking systems.

Measurement of relevant characteristics of the NBFIs involved in international debt securities financing is subject to far less transparency and data availability. The NBFI sector covers a very wide and diverse set of institutions and no consistently defined NBFI health measures are readily available. We take a novel approach to characterize the financial conditions of the institutions involved in international debt security markets. Our starting point is a set of classifications of non-bank financial intermediaries (NBFIs), from the Financial Stability Board (2024), whereby institutions are classified according to their engagement in five economic functions (see Table A2). Each economic function, by country, receives a score from the FSB along various dimensions, including leverage, measured as the ratio of total financial assets to equity.[3] Specifically, we construct shares of flows originated by NBFIs from different economic functions (EFs) at the home (lending) country level and then convert them into host (borrower) country measures using weights based on bilateral Coordinated Portfolio Investment Survey (CPIS) data. The home country level is an important dimension, since the composition of NBFIs in each country can be dramatically different. While institution-level data on these NBFI characteristics are not available on a comparable cross-country basis, we utilise country-level FSB data in order to analyze aggregate patterns.

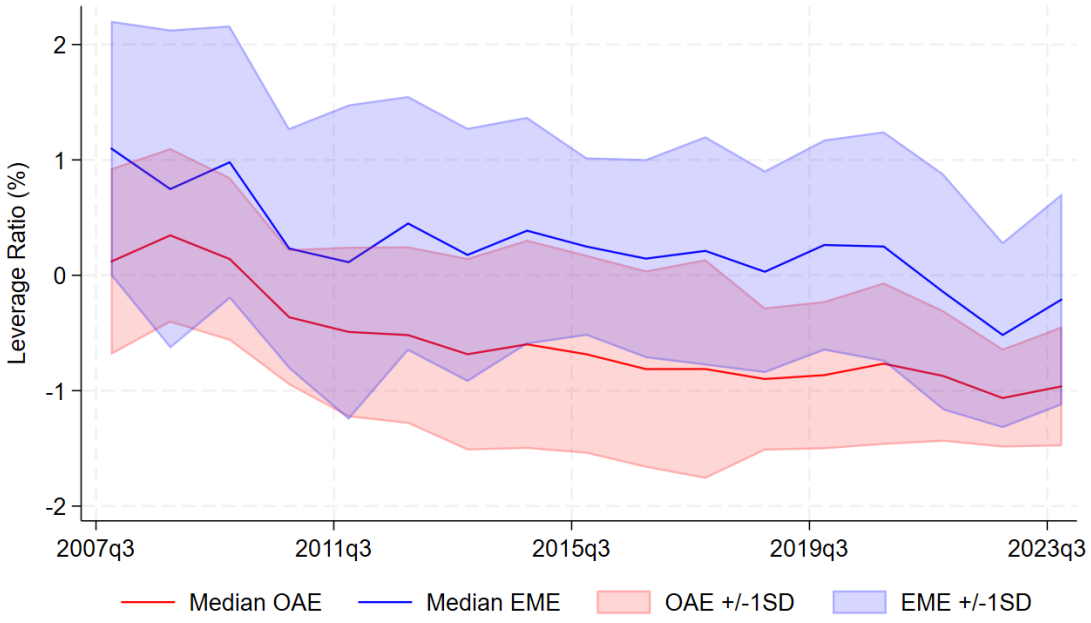
[3] Other dimensions include liquidity transformation, maturity transformation and credit intermediation (Financial Stability Board (2024)).

Graph 3: Bank Capitalization and NBFI Leverage of Financiers, Borrrowing Country Perspective

(a) Bank Capital Ratio



(b) NBFI Leverage



Notes: The graphs depict, by date, the median and one standard deviation (SD) band across countries of the demeaned Bank Capital Ratio and NBFI Leverage, for 2000Q1-2024Q1. Countries are divided into Other Advanced Economies and Emerging Market Economies.

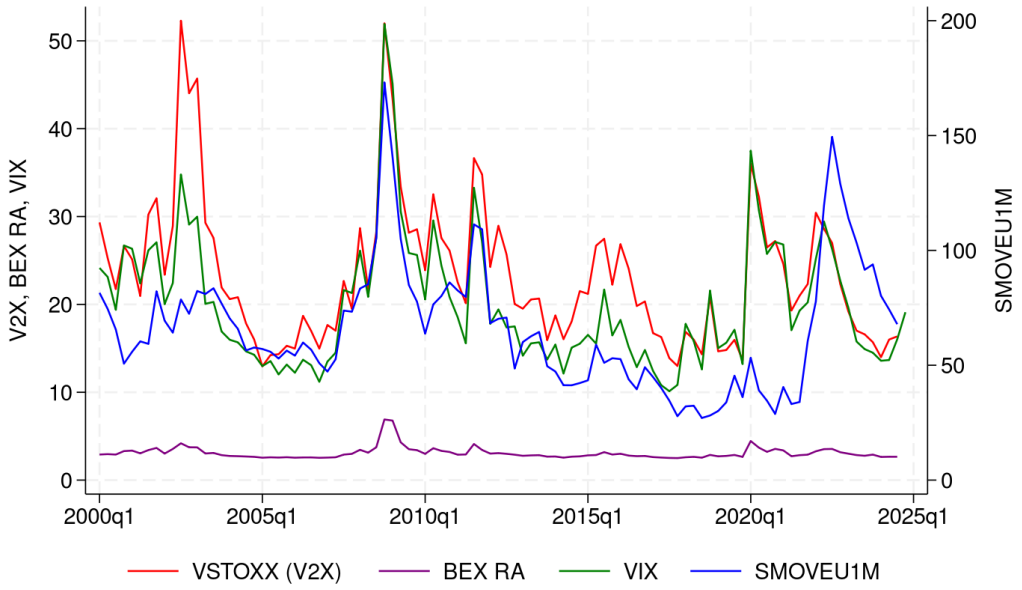
The resulting Banking system and NBFI lender characteristic series, as viewed from the vantage point of borrowing countries, are shown in Graph 3. The capital levels of banks financing OAEs tends to be lower than those providing financing to EMEs. However, these series move together showing that banking systems tended to expand capital shares through 2020 while exhibiting some reversion in the post pandemic period. The weighted mix of countries involved in EME bank lending is tilted toward banks that hold higher capital. There is substantially more variation in both the composition of NBFI lenders across OAEs and EMEs, and the implied leverage of financiers in this space as viewed from the borrower perspective. On average, the NBFIs providing international credit to EMEs tend to be more leveraged than those lending to OAEs. However, there is substantial overlap across country types by date.

3.3 Global and local factors

We capture changes in the stance of US monetary policy, a key global factor, using the Federal Funds rate or the shadow policy measure when relevant (Wu and Xia (2016) for Q1 2009 through Q4 2015 and Q3 2020 to Q2 2024). We follow the broader literature and in our baseline specifications proxy global risk conditions by the VIX index of the implied volatility in S&P500 stock index option prices from Chicago Board Options Exchange (CBOE). For robustness, we alternatively proxy risk conditions utilizing the distribution of realizations of the BEX RA measure of risk sentiment (Bekaert, Engstrom, and Xu, 2022), and the euro VSTOXX index and ICE BofAML Swap MOVE index both sourced from Bloomberg.[4] Albeit on a different scale, the VIX and BEX RA measures move most closely together, with strong overlaps of series peak dates (and top 25th and top 10th percentile observations). The VIX and MOVE series have a somewhat weaker comovement and have approximately a 30 percent overlap on which dates are in the top 25th and top 10th percentile of observations.

[4]The relative patterns of these indices are visualized in Graph 4.

Graph 4: Alternative Measures of Risk Conditions



Notes: VSTOXX (V2X) denotes the EURO STOXX 50 index and SMOVEU1M denotes the ICE BofAML Swap MOVE Index. VSTOXX and SMOVEU1M are sourced from Bloomberg. VIX is sourced from Chicago Board Options Exchange (CBOE). BEX is the Risk Aversion Index and is sourced from Bekaert, Engstrom, and Xu (2022).

The baseline specifications represent local factors by including three borrowing country variables: local real GDP growth, sovereign ratings, and the degree of financial openness. For each borrowing country, the sovereign ratings variable is defined as the average ratings across the three major credit rating agencies (S&P, Moody's and Fitch). The degree of financial openness is captured by the Chinn-Ito index (Chinn and Ito, 2008), normalized between 0 and 1.

4 Global Liquidity Responses to Global Factors

We provide initial facts by first estimating a baseline model of the relationship between the main global liquidity components (cross-border loans and international debt securities) and both global factors and local (or borrowing country-specific) drivers:

$$GrRateY_t^j = \beta_1 \Delta USMP_t + \beta_2 X_t^j \Delta USMP_t + \beta_3 logVIX_t + \beta_4 X_t^j logVIX_t + \beta_5 \Delta logGlobalGDP_t + \beta_6 \Delta SovRating_t^j + \beta_7 ChinnIto_t^j + \beta_8 \Delta logGDP_t^j + \beta_9 X_t + \mu^j + \varepsilon_t^j \quad (1)$$

where j denotes borrowing country and t is time. As in Avdjiev, Gambacorta, Goldberg, and Schiaffi (2020), this baseline specification considers the international capital flows and global liquidity drivers from the perspective of the borrowing country. Global liquidity is divided by instrument (cross-border loans and international debt securities) and by borrower sector (banks and non-banks), with these components explored separately and in aggregate. Y_t^j can be cross-border loans (to all sectors, to banks, to non-banks) or international debt securities (issued by borrowers in all sectors, by banks, or by non-banks). Following standard practice, the model is expressed in stationary variables to avoid problems of spurious correlations. The international flows on the left-hand side of the equation are expressed in growth rates $GrRateY_t^j$. All specifications include country fixed effects μ^j.

The right-hand-side of the equation contains the change in the US monetary policy rate and the log VIX to measure global risk conditions. The variable $USMP_t$ is given by the US Federal Funds Rate in normal times and the Wu-Xia shadow rate measure during the zero lower bound post-GFC period. Specifications include as control the global GDP and local factors corresponding to borrowing country j and flow type. Local controls include sovereign credit ratings $SovRating_t^j$, the level of the Chinn-Ito index of financial openness $ChinnIto_t^j$ (Chinn and Ito, 2008) and local GDP growth $logGDP_t^j$. Sovereign ratings proxy the role of country risk and the perceived creditworthiness of borrowers by country. The Chinn-Ito index gauges the degree of capital account openness. The Fed funds rate and the sovereign ratings are in first differences, while local and global GDP are in growth rates.

The model is estimated under the assumption that the two key global liquidity drivers, the Fed funds rate and the VIX, are exogenous when controlling for local and global GDP, government ratings and degree of financial openness. Moreover, the sensitivities to the VIX are allowed to differ across various dimensions of heterogeneity. Baseline specifications allow for different sensitivities for the OAEs and EMEs. Subsumed within vector X_t^j, a significant coefficient on interaction terms containing an EME dummy implies statistically different EME sensitivities from those of OAEs. Reporting of separate coefficients on so-called safe-haven economies is suppressed. When we depart from the baseline in the next sections, specifications introduce within X_t^j interactions the characteristics of types of (bank and non-bank) financial institutions intermediating global liquidity flows, with appropriately specified lag structures.

Notes: The sample includes quarterly data for 61 recipient countries (26 advanced economies and 35 emerging economies) over 2000:Q1 - 2024:Q1. The baseline coefficients on risk sensitivities exclude safe haven country effects. US MP is given by the Federal Fund Rate and by the Wu-Xia Shadow rate for 2009:Q1 – 2015:Q4. The regressions include ΔReal Global GDP and borrowing country controls (ΔReal GDP, ΔSovereign Ratings, Chinn-Ito Index). The regressions also include a full set of borrowing country fixed effects. Specifications are winsorized at the 1% level.

Baseline results: As a first step, the baseline specification in equation (1) is estimated over the full data sample (2000:Q1 – 2024:Q1), taking the perspective of quarterly flows into borrowing countries and sectors. The key estimated coefficients are in line with conventional priors. The estimated impacts of the US monetary policy and global risk conditions on the main global liquidity components are both negative and statistically significant for most borrowing country groups and sectors (Table 1). Tests of two dimensions of heterogeneity are included in this baseline, conducted across the dimensions of categories of global liquidity (CBL, IDS, sum of CBL and IDS) and of borrowing country sectors (banks and non-banks). Tighter US monetary policy is associated with lower growth in both, cross-border bank loans and international bond issuance.

Similarly, during periods in which risk aversion (measured by the VIX) is higher, the growth rates of cross-border loans and international bond issuance tend to be lower. Using this baseline specification and this full data time frame, sensitivity comparisons for EMEs contrast with those for OAEs. Cross-border bank loans sensitivity to risk for all sectors does not differ significantly for OAEs and EMEs. By contrast, the financing of international debt securities is considerably more risk sensitive for EMEs than the issuance done by OAE borrowers.

Time variation: Using the baseline specification, we next document heterogeneity in risk sensitivities along the time dimension. Following the approach of Avdjiev, Gambacorta, Goldberg, and Schiaffi (2020), the coefficients in the benchmark specification are subject to a structural break.[5] Tests confirm that the break date for both main global liquidity components (cross-border loan flows and international bond flows) is 2009:Q1. We proceed by investigating the post-GFC evolution of the key sensitivities to global risk by sequentially estimating equation (1) with a break in 2009:Q1, starting with data for 2000:Q1 – 2013:Q1 to reflect risk sensitivity differences in the early post GFC period, and then add one quarter at time until we reach the full sample period (2000:Q1 – 2024:Q1). This procedure generates a distinct set of parameter estimates for each possible post-GFC time window that has an end-quarter from 2013:Q1 to the sample period end (2024:Q1).

[5] Rather than exogenously imposing an ad-hoc break date, we test for its presence and exact timing endogenously, using the tools developed in Bai (1994, 1997); Kurozumi (2002); Carrion-i Silvestre and Sansó (2006).

Notes: The sample includes quarterly data for 61 recipient countries (26 advanced economies and 35 emerging economies) over the period 2000:Q1 - 2024:Q1. The baseline coefficients on risk sensitivities exclude safe haven country effects. The regressions include ΔReal Global GDP, US MP and borrowing country controls (ΔReal GDP, ΔSovereign Ratings, Chinn-Ito Index). US MP is given by the Federal Fund Rate and by the Wu-Xia Shadow rate for 2009:Q1 – 2015:Q4. The regressions also include a full set of borrowing country fixed effects. Specifications are winsorized at the 1% level.

Estimated sensitivities to the VIX for the EME and OAE borrowers (without distinguishing the sector being funded) during the three key time windows are provided in Table 2. These results show that EME sensitivities to risk have historically been stronger than those for OAEs, and that the post GFC period is left with risk sensitivities concentrated in IDS and EMEs.

Elaborating on time variation results, Graph 5a and Graph 5b plot the estimated sensitivities to global risk, with a breakdown by instrument (loans and bonds), by borrowing country (advanced and emerging) and by borrowing sector (all sectors, banks, non-banks). These visualizations respectively pertain to other advanced economies, and of emerging market economies as borrowers experiencing risk sensitivity in components of global liquidity. Within each panel, the solid purple line is the sensitivity to risk in the pre-GFC period. The other lines show the quarter-by-quarter estimated risk sensitivity and a one standard deviation interval for these estimates.

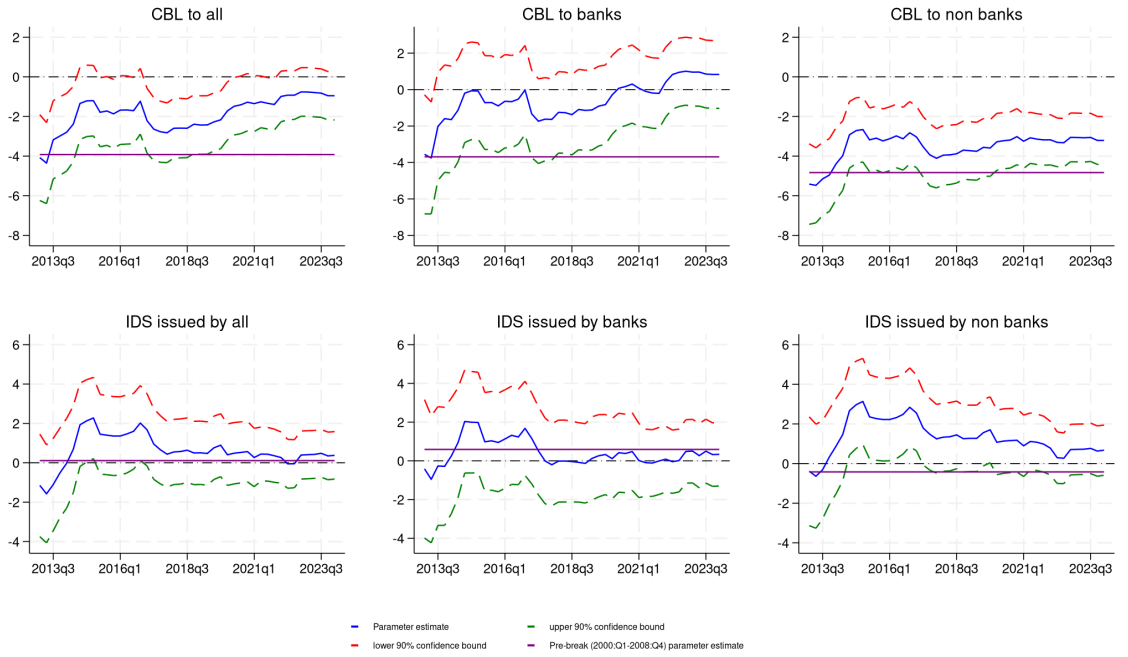
The upper panels on cross-border loans show that overall risk sensitivities of these funding flows from global banks are smaller in magnitude in the post-GFC period, compared with pre-GFC. For advanced economies, this reduced sensitivity was particularly strong for inter-bank lending. Indeed, this type of risk response became insignificantly different from zero. For EMEs the same outcome occurred with respect to interbank lending activity, from pre-GFC level of sensitivity that was even stronger than for OAEs. For EMEs, there also was a starker decline in the risk sensitivity of cross-border lending to nonbank borrowers.

The lower panels of these exhibits show the time variation in estimated sensitivities of IDS for OAEs and then for EMEs. Recall that volumes of these flows were small relative to bank lending pre-GFC. For OAEs, the estimated risk sensitivities for IDS are insignificantly different from zero pre- and post-GFC. Meanwhile, IDS risk sensitivities for EMEs stay both significantly negative very close to pre-GFC values, and with considerable variation particularly with respect to funding for bank borrowers in EMEs.

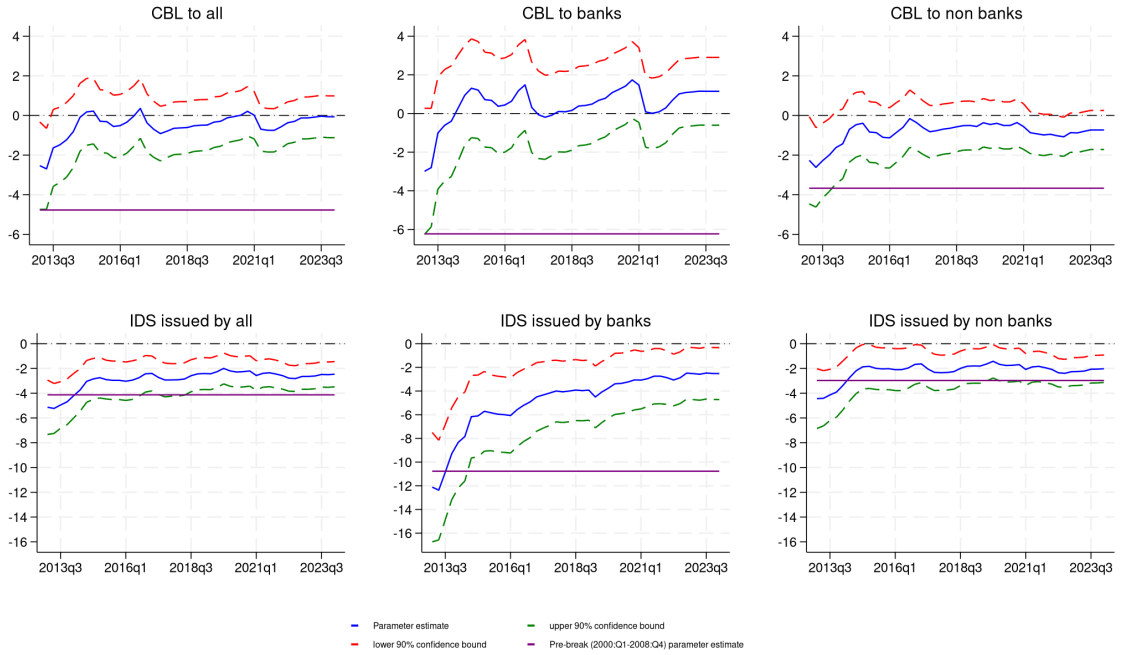
Our prior research had already emphasized that the sensitivity of cross-border bank lending to global risk aversion declined dramatically after the GFC, with sharply moderated credit supply contractions in the context of elevated risk conditions (Avdjiev, Gambacorta, Goldberg, and Schiaffi, 2020). In line with this, the results presented in Table 2 and Graph 5a-5b also reveal that the estimated impact of the VIX on CBL, which was negative and strongly statistically significant before the GFC, declined considerably during the post-GFC period and lost its statistical significance.

Graph 5: Post-break sensitivities to log (VIX), evolution over time

(a) Other Advanced Economies (excluding safe havens)



(b) Emerging Market Economies



Notes: The graph shows the evolution over time of sensitivities to the log (VIX) for borrowers using recursive estimations of equation 1. For each quarter t, the charts show the post-break coefficient (and its 90% confidence interval) obtained by estimating the model with a sample from 2000:Q1 up to quarter t, with a break in 2009:Q1. The purple line in each panel represents the pre-break estimate of the sensitivity to VIX. Sources: authors' calculations.

The reduction in the effects is quantitatively relevant. The impact of a 1 per cent increase in the VIX on cross-border loans declined from 4 per cent (before the GFC) to 1 per cent (after the GFC) for OAE borrowers and from 5 per cent to 0 per cent for EME borrowers.

In contrast to cross-border loans, international bond issuance did not experience a significant change in its sensitivity to global risk aversion. The impact of the VIX on the sensitivity of international debt securities issued by residents of OAE remained insignificant throughout the entire sample period (both before and after the GFC). Meanwhile, the global risk sensitivity of IDS issued by EME borrowers remained negative and statistically significant (at roughly the same levels) before and after the GFC. More precisely, the impact of global risk aversion on international bond issuance by EME borrowers briefly went from 4 per cent pre-crisis to 6 per cent in the immediate aftermath of the GFC and then returned back to 4 per cent shortly after the 2013 Fed Taper tantrum. By contrast, the respective global risk sensitivity for OAE international bond issuers remained insignificant throughout the entire sample.

5 Drivers of fluctuations in global risk sensitivities

Conjecture 1 posited that the composition of the financial institutions supplying global liquidity flows matters for risk sensitivity of these flows to the extent that the balance sheet constraints faced by these institutions bind risk-taking. The risk sensitivity of funding flows should be stronger (more negative) when funding is (in aggregate) provided by financial intermediaries that face tighter capital and leverage constraints. The scope of the empirical investigation in this paper is broader than that in the existing literature, which focused solely on cross-border bank lending and only on bank capital (Avdjiev, Gambacorta, Goldberg, and Schiaffi, 2020), without distinguishing borrowers in safe havens from borrowers in other advanced economies and emerging markets, and without conditioning on the borrowing sector and on the relative importance of international debt securities. Accordingly, the results provided in this section considerably expand the evidence relevant for understanding the drivers of the variation in the global risk sensitivities of the main global liquidity components.

Recall also that *Conjecture 2* posits that risk migration, taking the form of activity shifting and movement of riskier borrowers from banks to NBFIs is associated with greater sensitivity of

aggregate global liquidity to global risk. The post-GFC strengthening of global bank regulatory standards increased banks' marginal costs of holding riskier assets. This should, all else the same, generate migration of riskier borrowers to IDS markets, where the main suppliers of funding are NBFIs, which did not face a similar post-GFC regulatory tightening. The migration of risky borrowers from banks towards NBFIs when bank capital constraints are tighter should have affected the marginal risk sensitivities of both, CBL and IDS flows. The post-GFC decline in the average riskiness of bank borrowers should have led to a fall in the global risk sensitivity of cross-border bank loans. Meanwhile, the global risk sensitivity of IDS should have also declined, if the borrowers that were no longer served by banks were less risky than the average IDS borrower.

We test these conjectures by estimating a modified version of the benchmark regressions in which global risk aversion is interacted with measures of the financial health of the two main types of financial intermediaries (banks and NBFIs) supplying global liquidity and a risk migration proxy. These metrics are associated with the lending institutions but viewed from the vantage point of the composition of financiers for each borrowing country and sector at each point in time. Banking sector constraints are proxied by the (lagged) capitalization levels of the lending national banking systems. NBFIs constraints are proxied by the (lagged) levels of leverage for that sector. For each borrowing jurisdiction, we use a weighted average of the financial health metric, where the weight assigned to each lending financial system for each borrowing country is equal to the lending system's share of cross-border financing to that borrowing country. The health measures enter the regressions in deviations from their respective sample means. Moreover, for each borrowing country j and time period t, we proxy risk migration from CBL to IDS markets by the IDS share of aggregate global liquidity: $IDSshare_t^j = IDS_t^j/(IDS_t^j + CBL_t^j)$. We construct a borrowing country-specific vector H_t^j, which consists of the above (bank and NBFI) financial health metrics and the IDS share. We then insert H_t^j in our benchmark equation as a standalone term and as an interaction with the VIX.

$$GrRateY_t^j = \beta_1 \Delta USMP_t + \beta_2 logVIX_t + \beta_3 H_t^j + \beta_4 logVIX_t * H_t^j + \beta_5 \Delta logGlobalGDP_t + \beta_6 \Delta SovRating_t^j + \beta_7 ChinnIto_t^j + \beta_8 \Delta logGDP_t^j + \beta_9 X_t + \mu^j \quad (2)$$

Table 3 provides the empirical results for the cross-border bank lending, distinguishing All Borrowing Countries, Other Advanced Economies, and Emerging Market Economies. Covering the full time frame from 2000Q1 through 2024Q1, and 61 borrowing countries overall, cross-border lending is consistently depressed when risk conditions are adverse. Bank capital is a robust driver, with higher capitalization rates for sources of funds associated with consistently lower risk sensitivities. This is in line with our conjectures and with the findings of Avdjiev, Gambacorta, Goldberg, and Schiaffi (2020). Intuitively, bank capital acts as a buffer against shocks and can dampen the impact of spikes in global risk aversion on bank lending, in general, and on the cross-border bank loan origination in particular (Gambacorta and Shin, 2018). Activity migration to IDS also consistently reduces the risk sensitivity of cross-border bank lending, in line with *Conjecture 2*.

The effects of bank capitalization and risk migration are not only statistically significant but also economically meaningful. The estimated coefficients (on the standalone VIX term and on the interaction term between the VIX and bank capitalization) for the benchmark sample of all borrowers (Table 3, Column 3) imply that increasing the capitalization levels of lending banks by one standard deviation would fully offset the negative impact of global risk on cross-border bank lending. Meanwhile, a one-standard deviation increase in the IDS share reduces the global risk sensitivities of CBL flows by half. Furthermore, the inclusion of the IDS share as risk migration proxy in the regression considerably enhances its overall fit (for example, in the regressions for all borrowing countries the R2 goes from 0.084 to 0.099).

We also estimate additional borrower sector-specific versions of the above specifications (Table B1 and Table B2). They deliver the same patterns of statistical significance as the aggregates presented in Table 3. Both, bank capitalization and IDS share deliver quantitatively and qualitatively stronger risk-stabilization effects for bank borrowers than for non-bank borrowers.

Table 4 investigates the drivers of the time variation in the global risk sensitivities of international debt securities. The interaction term between NBFI leverage and the VIX has a negative and statistically significant coefficient in the regression specifications estimated on our benchmark sample of all borrowing countries. This suggests that higher NBFI leverage amplifies the sensitivity of international debt securities to global risk - a set of results consistent with *Conjecture 1* and complementary to the bank capital results (Table 3). Since highly leveraged NBFIs have smaller buffers against contingencies triggered by shocks, their IDS holdings are more sensitive to fluctua-

tions in global risk aversion. The respective coefficients for the two main borrowing country groups are also negative. They are statistically significant for other advanced economies but noisier for EMEs. Meanwhile, our proxy for risk migration (the interaction term between the VIX and the IDS share) is once again positive and significant for the benchmark sample of all borrowing countries. This provides further evidence in support of *Conjecture 2*. This interaction term is also positive and statistically significant for EMEs. It is not significant for OAE borrowers. The additional borrowing sector-specific regressions we estimate reveal that the above results appear to be driven by non-bank borrowers (Table B3 and Table B4).

The economic magnitudes of the coefficients presented in Table 4 are also substantial. The results for the full sample (Column 3) suggest that the global risk sensitivity of IDS flows to a country whose NBFI lenders have leverage that is one standard deviation below the global mean would be only half of the respective sensitivity for the average country in our benchmark sample. Moreover, a one-standard deviation increase in the IDS share is associated with a 70% reduction in the global risk sensitivity of IDS flows.

Next, we examine the effect of each of the above characteristics on the risk sensitivity of aggregate global liquidity flows. Table 5 reports the distinction between OAE and EME, while the analysis for all borrowing countries is reported in Table A3 in the Appendix. The results from this exercise are consistent with those from Table 3 and Table 4 as well as with our main conjectures. In line with their respective effects on the main global liquidity components (CBL and IDS), higher bank capital and lower NBFI leverage dampen the sensitivity of aggregate global liquidity flows to global risk conditions. These results are also fully in line with *Conjecture 1*. Moreover, a greater IDS share is associated with lower global risk sensitivities of AGL flows. This set of results provides even stronger evidence in support of *Conjecture 2*. It suggests that the compositional effects (associated with the migration of borrowers with certain risk profiles from CBL to IDS markets) driving this conjecture are not only present, but also strong enough to dominate the mechanical effect of IDS flows (which tend to be more risk sensitive than CBL flows, at least in the post-GFC period) getting a greater weight as the IDS share rises. These findings also are consistent at the level of sectoral breakdowns (Table B5 and Table B6).

The baseline coefficients on risk sensitivities exclude safe haven country effects. Bank capital is given by the lagged bank equity to total assets ratio in deviation from its sample mean. The NBFI leverage is lagged and in deviation from its sample mean. IDS share is given by the share of international debt securities (IDS) in country's total borrowing. The regressions include US MP, and borrowing country controls (ΔReal GDP, ΔSovereign Ratings, Chinn-Ito Index). US MP is given by the Federal Fund Rate (the Wu-Xia Shadow rate for 2009:Q1 – 2015:Q4). The regressions also include a full set of borrowing country fixed effects. Specifications are winsorized at the 1% level.

The results presented in Table 5 are quantitatively similar to those presented in Table 3 and Table 4. Increasing the capitalization levels of lending banks by one standard deviation would fully offset the negative impact of global risk on AGL flows to OAE borrowers and would decrease the respective impact on EME borrowers by roughly two thirds. Meanwhile, decreasing the NBFI leverage by one standard deviation reduces the global risk sensitivity of AGL flows by 60% for OAE borrowers and by 30% for EME borrowers. Finally, a one-standard deviation increase in the IDS share reduces the global risk sensitivities of AGL flows by 25% for OAE borrowers and by 20% for EME borrowers.

Risk shifting can also be a direct product of regulatory arbitrage. Houston, Lin, and Ma (2012) find that banks may circumvent domestic activity restrictions and stringency of capital regulation and take excessive risks by increasing funding flows to locations with weaker regulations, identified after controlling for economic legal and institutional factors. Frame, Mihov, and Sanz (2020) identify more banking subsidiary use in countries with weaker regulation. When acquisitions occur across borders, acquiring banks tend to be from countries with stronger levels of regulation than the acquired banks. On the lending side, banks are less likely to originate a loan in a country with more stringent capital regulation, conditional on originating a loan (Demirgüç-Kunt, Horváth, and Huizinga, 2023).[6] These effects are stronger for weakly capitalized banks and for riskier borrowers. Loan location choice trades off weaker regulation and more efficient information acquisition.

6 Robustness

The robustness of these benchmark results has been checked in several ways. First, we consider whether the core results generated using the VIX are robust to using three alternative indicators of risk. Second, as our baseline specifications use a measure of US monetary policy that is constructed by combining the Federal Funds rate with the Wu-Xia shadow rate during zero lower bound periods, we compute alternative results using the Wu-Xia for the full sample period. A third category of robustness tests is an alternative specification for introducing bank capitalization, NBFI leverage, and international debt securities share (IDS share) into regression specifications, so that in this new specification, IDS share interacts with these variables. As extreme risk and

[6] Results are based on analysis of micro-data on syndicated loan origination and the international subsidiary level of multinational banking groups, covering 10 source countries and for 1999-2014.

crisis period considerations are identified as having particular dynamics, we examine the effect of splitting particularly high or extreme risk periods from the business as usual values of risk.

6.1 Alternative risk measures

While our baseline specifications proxy global risk conditions by the VIX index of the implied volatility in S&P500 stock index option prices, the robustness checks utilize respectively the BEX RA measure of risk sentiment (Bekaert, Engstrom, and Xu, 2022), the euro VSTOXX index, and MOVE index. More concretely, we re-estimate the regressions presented in Table 1 (baseline) and Table 5, on financial institution health metrics as contributors to global risk sensitivity. Tables of robustness results are provided in Appendix C.

Regression tables using the alternative measures of global risk all reproduce the main findings that the effect of global risk conditions on the main global liquidity components are both negative and statistically significant for most borrowing country groups and sectors, albeit with some differences in patterns of statistical significance. Moreover, across measures the finding is robust that the sensitivity of liquidity flows to global risk tends to be higher for EME borrowers, with some differences for loans and bonds across the different risk measures (Table C1, Table C2, and Table C3). For both OAEs and EMEs, results are also consistent across risk proxies in the sensitivity of CBL to global risk, which continue to show important roles for bank capitalization, NBFI leverage and the IDS share (Table C4, Table C5, and Table C6).

6.2 Monetary policy variable choice

Alternative specifications use Wu-Xia for the full sample period, in lieu of using it only during zero lower bound periods. This alternative specification does not significantly influence the sign or significance patterns of risk sensitivity along any of the dimensions of heterogeneity that we examine (Table C7 and Table C8).

6.3 Alternative specification using IDS Share

The baseline specifications introduced the share of financing accounted for by international debt securities as a stand-alone term and in an interaction term with the VIX. We interpret this as a separate risk migration proxy. However, an alternative specification could treat the actual effects

of bank capital and of NBFI leverage on VIX sensitivities as changing over time as the importance of NBFIs versus banks evolves. In this case, IDS would interact with these sensitivities, beyond the direct additive effects. Accordingly, triple interaction terms enter the regression specifications. Our alternative regression specifications show that these triple interaction terms generally are not significant for risk sensitivities in cross-border loans and that our key results are robust to their inclusion in all specifications.[7]

6.4 Business as usual versus high stress periods

As a final robustness check, we explore whether the risk sensitivity results are driven primarily by the extreme risk periods, or if these sensitivity evolutions likewise characterize more business-as-usual values of the VIX index. Prior research by Chari (2023), Chari, Dilts Stedman, and Lundblad (2021, 2022), and Forbes and Warnock (2012, 2021) stresses that risk responses and flow dynamics are fundamentally different in high-risk periods compared with times characterized as business-as-usual. Accordingly, in this section we test the robustness of our main results about risk sensitivity to including or excluding the most extreme values of the VIX (top 10th percentile) from the regression specifications.

Many of the key coefficients retain their sign and statistical significance during business-as-usual periods. Nevertheless, baseline regression results show a few interesting differences in global liquidity risk sensitivities when the results over the full sample of observations are compared with results excluding extreme stress periods as indicated by high VIX (compare Table 1 with Table C9). For other advanced economies, risk sensitivities tend to be quantitatively weaker outside of the high stress periods. Moreover, some categories of flows to OAE borrowers show weakly positive coefficients on risk sensitivity - for example cross-border loans to banks and IDS flows to non-banks. By contrast, the global risk sensitivities of flows to EMEs are smaller when peak VIX periods are excluded, but qualitatively similar to those estimated in the full-sample regressions. Another interesting finding is that, for EMEs, the moderating effects on risk sensitivities of higher funding bank capitalization and lower NBFI leverage appear to be statistically important only when high stress periods are included in the estimation (compare the results in Table 5 with those in Table C10).

[7] The results for these robustness specifications are available from the authors upon request.

7 Conclusions

Risk conditions are a key global factor driving patterns in international financial flows. This paper has documented sensitivities of global liquidity to risk from the perspective of countries with a different level of development and institutional design. In particular, we controlled for the particular characteristics of "safe haven" countries (that receive positive international capital flow pressures when risk is elevated), and focused our comparison between Other Advanced Economies and Emerging Market Economies. We provided evidence that risk sensitivities differ for cross-border loans versus international bonds, across borrowing country groups (OAE vs EME), and by banking sector versus non-bank private sector borrowers. Balance sheet constraints originating in funding source countries are important for financial flow sensitivities of destination countries, pointing to the prevalence of financial frictions. Balance sheet constraints apply to both bank and non-bank financial firms involved in sourcing global liquidity. Higher capitalization rates of banks and lower leverage levels of non-bank financial institutions are associated with lower risk sensitivities of global liquidity.

We also provide evidence that the migration of risk between the two main global liquidity components - cross-border loans and international debt securities - has two effects on the risk sensitivity of aggregate global liquidity flows. The first effect is compositional. If banks become less willing to extend loans to risky borrowers, the cross-border lending sensitivity to global risk should decline (since the average riskiness of bank borrowers would fall). Furthermore, the global risk sensitivity of international debt funding should also decline, if the borrowers that are no longer served by banks are less risky than the *ex ante* average borrower using international debt securities (despite being riskier than the average bank borrower). The second effect is mechanical. Borrower migration from banks to debt markets should mechanically increase the sensitivity of aggregate flows to global risk when IDS has a greater weight than cross-border bank loans. We document that since the first (compositional) effect dominates the second (mechanical) effect, an increase in the share of international debt securities share of flows is associated with a fall in the risk sensitivities of aggregate global liquidity flows.

Our results shed light on why the risk sensitivities for the main global liquidity components diverged starkly since the Global Financial Crisis. The sensitivity of cross-border bank loans

to global risk shifted from being significantly negative before the crisis to becoming statistically insignificant afterwards. By contrast, the global risk sensitivity of international debt securities issued by emerging market borrowers remained considerably elevated before and after the crisis, while the risk sensitivity of debt securities issued by other advanced economy borrowers stayed insignificant.

Finally, our evidence shows that the post-GFC shifts in the composition of the main global liquidity components (cross-border loans and international bonds), as well as the fluctuations in their respective sensitivities to global risk, are related to the tightness of the balance sheet constraints they face and to the migration of risky borrowers across funding sources. These changes occurred against the backdrop of the still relatively loose regulatory framework for non-bank financial institutions.

Notes: The sample includes quarterly data for 61 recipient countries (26 advanced economies and 35 emerging economies) over the period 2000:Q1 - 2024:Q1. The baseline coefficients on risk sensitivities exclude safe haven country effects. Bank capital is given by the lagged bank equity to total assets ratio in deviation from its sample mean. The NBFI leverage is lagged and in deviation from its sample mean. IDS share is given by the share of international debt securities (IDS) in country's total borrowing. The regressions include US MP, and borrowing country controls (ΔReal GDP, ΔSovereign Ratings, Chinn-Ito Index). US MP is given by the Federal Fund Rate (the Wu-Xia Shadow rate for 2009:Q1 – 2015:Q4). The regressions also include a full set of borrowing country fixed effects. Specifications are winsorized at the 1% level.

Notes: The sample includes quarterly data for 61 recipient countries (26 advanced economies and 35 emerging economies) over 2000:Q1 - 2024:Q1. The baseline coefficients on risk sensitivities exclude safe haven country effects. US MP is given by the Federal Fund Rate and by the Wu-Xia Shadow rate for 2009:Q1 – 2015:Q4. The regressions include ΔReal Global GDP and borrowing country controls (ΔReal GDP, ΔSovereign Ratings, Chinn-Ito Index). The regressions also include a full set of borrowing country fixed effects. Specifications are winsorized at the 1% level.
